ABSTRACT

Background Total body hypothermia is an established neuroprotectant in global cerebral ischemia. The role of hypothermia in acute ischemic stroke remains uncertain. Selective application of hypothermia to a region of focal ischemia may provide similar protection with more rapid cooling and elimination of systemic side effects. We studied the effect of selective endovascular cooling in a focal stroke model in adult domestic swine.

Methods After craniotomy under general anesthesia, a proximal middle cerebral artery branch was occluded for 3 h, followed by 3 h of reperfusion. In half of the animals, selective hypothermia was induced during reperfusion using a dual lumen balloon occlusion catheter placed in the ipsilateral common carotid artery. Following reperfusion, the animals were sacrificed. Brain MRI and histology were evaluated by experts who were blinded to the intervention.

Results 25 animals were available for analysis. Using selective hypothermia, hemicranial temperature was successfully cooled to a mean of 26.5±C. Average time from start of perfusion to attainment of moderate hypothermia (<30°C) was 25 min. Mean MRI stroke volumes were significantly reduced by selective cooling (0.050±0.059 control, 0.005±0.011 hypothermia (ratio stroke:hemisphere volume) (p=0.046). Stroke pathology volumes were reduced by 42% compared with controls (p=0.256).

Conclusions Selective moderate hypothermia was rapidly induced using endovascular techniques in a clinically realistic swine stroke model. A significant reduction in stroke volume on MRI was observed. Endovascular selective hypothermia can provide neuroprotection within time frames relevant to acute ischemic stroke treatment.

INTRODUCTION

Hypothermia is the oldest and best studied neuroprotectant. Animal and human studies have established its benefit.1–13 Pioneering surgical investigators recognized the potential for deep whole body hypothermia to protect against focal ischemia, but noted significant side effects.14–16 These challenges led a few early investigators to pursue selective hypothermia applied only to the region of ischemia.17–19 Advances in endovascular technology have rekindled interest in the selective approach. Human trials, such as Cooling for Acute Ischemic Brain Damage (COOL AID) and Intravascular Cooling for the Treatment of Stroke–Longer window (ICTuS-L), as well as animal studies, suggest that applying selective hypothermia using an endovascular approach could provide rapid induction of therapeutic hypothermia within a meaningful time frame in focal cerebral ischemia.7 9 18–22

In this study, we investigated catheter based selective brain hypothermia in an adult domestic swine model of stroke. We wished to determine whether moderate selective brain hypothermia could be rapidly induced using percutaneous endovascular technology, and whether stroke volumes could be reduced compared with a control group. Our model consisted of temporary transcranial occlusion of the middle cerebral artery (MCA) followed by percutaneous placement of a novel endovascular cooling catheter to provide selective hemicranial cooling during reperfusion.

METHODS

Setup and craniotomy

Under an approved animal research protocol (Schulich School of Medicine and Dentistry Animal Use Protocol 2009-079) and following Canadian Council of Animal Care guidelines, 28 Yorkshire-Landrace-cross pigs (50 kg) were assigned to normothermia or hypothermia in a 1:1 alternating fashion. Following acclimation in an approved vivarium for 48 h, animals were anesthetized using 1–2 mL of intramuscular Telazol (Fort Dodge, Iowa, USA), intubated, and maintained with a nitrous oxide–isoflurane mixture. Arterial and central venous monitoring was obtained via bilateral transfemoral 6 F sheath placement, and a right fronto-orbital craniotomy was performed.23 After opening the arachnoid to release CSF, the head of the bed was elevated to provide maximal brain relaxation. Mannitol was avoided to eliminate any confounding neuroprotective effects.24 25 Under high surgical magnification, a temporary aneurysm clip was applied to one of the two to three MCA branches running beneath the posterior frontal lobe. After 3 h of occlusion, the clip was removed and the scalp closed.

Selective brain cooling

Hypothermia animals were turned supine immediately following skin closure. Under fluoroscopy, an arterial 6 F sheath was exchanged over a series of dilators for the 14 F outer flow lumen (OFL) of the TwinFlo catheter (Thermopeutix Inc, San Diego, California, USA) (figure 1). The OFL was positioned in the descending thoracic aorta. Thereafter
activated clotting time was maintained at least two times normal using intravenous heparin. The 9.5 F inner flow lumen (IFL), a dual lumen balloon catheter, was introduced through the OFL and navigated into the right common carotid artery (ipsilateral to the ischemic hemisphere). The OFL and IFL ports were attached to an extracorporeal circuit (Maquet Rotoflow pump, Jostra chiller, Medtronic Myotherm heat exchanger), and extracorporeal circulation was established using a starting temperature of 25°C. The IFL balloon was then inflated to radiographic occlusion of the artery. Pressure monitoring from the distal end of the IFL and inflow rates at the extracorporeal circuit were checked to avoid excessive perfusion pressures or flow rates. Inflow temperature was decreased in increments of 5°C to rapidly achieve hypothermia while maintaining hemodynamic stability. Extracorporeal cooling via the common (rather than the internal) carotid artery was deliberate in order to cool the brain using both direct and indirect pathways. Hemodynamic parameters (core temperature, heart rate, mean arterial blood pressure) and arterial blood gases (oxygen, hemoglobin, glucose, pH) were continuously evaluated. The decision as to the depth of hypothermia was made on clinical grounds, based on the animal’s hemodynamic stability. Perfusion was terminated once 3 h of reperfusion was completed.

**Temperature measurements**

Core temperatures were measured via rectal and esophageal thermometers. Nasal temperatures were used as a surrogate for brain temperature to avoid trauma from intraparenchymal probe insertion during the full anticoagulation required for the endovascular procedure. In the first selective hypothermia case, we found that subdural temperature measurements were within 2°C of transnasal measurements.

**Euthanasia, brain fixation, and analysis**

Following 3 h of reperfusion, the animal was euthanized with 108 mg/kg of Euthanyl Forte (Bimeda-MTC, Cambridge, Ontario, Canada). Fixation of the brain in situ with 500 mL of 10% neutral buffered formalin (EMD, Baltimore, Maryland, USA) was achieved using the IFL balloon catheter. The brain was removed for imaging and histology. MRI was performed postmortem and reviewed by a neuroradiologist blinded to the intervention. T2 and T1 three-dimensional sagittal images were obtained (T2 TR9700, TE 82.2 and TE 143 (142.7), 2 mm slice thickness, 16 cm FOV, 256×256 matrix; T1 TR 8.5, TE 3.5, 1.2 mm slice thickness, 12 cm FOV, 256×256 matrix). T2 data were used because diffusion information was lost at death. The area of T2 signal abnormality on each axial slice was determined using Osirix. Contiguous axial slices with T2 signal abnormality were summed to provide a total volume. An identical method of calculating hemispheric volume, excluding the midbrain, was performed, and the ratio of stroke volume to hemisphere volume was determined as a percentage. Next, the fixed cerebrum was sliced into 1 cm thick coronal slices and placed in cassettes for paraffin embedding. Pathological examination was conducted by a neuropathology team blinded to the intervention. Coronal slices of the cerebrum were stained with hematoxylin and eosin. Ischemic change was defined as the presence of both dark neurons and perineuronal vacuolation. The area of the ischemic change was determined manually, and then multiplied by the block thickness to give a volume.

**Statistics**

In the initial sample size calculation, it was estimated that 70% of animals in the normothermic group would have infarction of at least 20% of the cerebral hemisphere volume. Assuming that selective hypothermia provides a marked reduction in the proportion infarcted, from 70% to <30% (or 6/20 animals), according to Fisher’s exact test, the two tailed p value will be <0.02 and the association between hypothermia and reduction in stroke will be considered statistically significant. Thus we initially planned for 20 animals in each group.

Hemodynamic parameters and arterial blood-gas values were compared using analysis of covariance. Changes in core temperature were compared using paired t tests. Between group comparisons of stroke volume were made using unpaired t tests or, where variances were unequal, using a Wilcoxon two sample test. Data were analyzed by an independent statistician using SAS V9.3, and p values <0.05 were considered statistically significant.

**RESULTS**

Twenty-eight pigs were studied. One died due to pre-existing pulmonary artery stenosis and hypertrophic cardiomyopathy. Two pigs were unusable due to inadvertent brain contusions during exposure, and no ischemia was induced. Twenty-five animals were available for analysis, consisting of 13 control and 12 selective hypothermia cases. There was one aortic dissection in the selective hypothermia arm. Differences in systemic parameters between controls and hypothermic animals were seen only in core temperature (p<0.001) and in pH (p<0.001) during the 3 h reperfusion–cooling phase of the experiment. However, core temperatures did not decrease below mild hypothermic levels (32–34°C) (table 1). The pH was 7.34±0.18 in the hypothermia cohort compared with 7.44±0.03 in the control group.

**Selective brain cooling**

The mean ipsilateral (right) hemicranial temperature decreased from 38°C to 26°C, while the contralateral (left) temperature decreased to 31.6°C during selective hypothermic perfusion (table 1). The average time to place the catheters and establish extracorporeal circulation was over 1 h but varied widely.

Effectiveness of selective hypothermia

Selective hypothermia reduced stroke volumes despite a significant delay in intervention (3 h of ischemia, mean 4.5 h from ischemia onset until moderate hypothermia). This was statistically significant for MRI stroke volumes. A similar trend was found for pathological stroke volumes but was not significant due to the wide variation in stroke volumes in our model. This may be a feature of our model, but is also seen in human clinical studies. Previous investigations of selective hypothermia examined subjects concurrently exposed to ischemia and hypothermia and have shown neuroprotective effects by clinical examination, radiology, and histology. Studies in rodents suggest that stroke may be ameliorated even when hypothermia is applied in a delayed fashion. Proposed mechanisms for this benefit include the protection of 'Penumbra' neurons at the peripheral zone of ischemia, suppression of excitatory neurotransmitters, and suppression of leukotrienes. During reperfusion with hypothermia, there are measurable reductions in ischemic metabolites, such as lactate and high energy phosphates, and reduction in one form of blood–brain barrier disruption.

DISCUSSION

Selective endovascular cooling for acute ischemic stroke

Animal studies of hypothermia have shown benefit during both global and focal cerebral ischemia. Human trials have demonstrated that hypothermia is beneficial in ameliorating global brain ischemia following cardiac arrest. Whether there is any role for hypothermia after focal ischemic stroke is uncertain. Whole body surface cooling requires hours to perform and is therefore impractical for acute stroke care. Both COOL AID and ICTUS-L trials achieved rapid hypothermia via endovascular transvenous cooling. Whole body hypothermia is limited to mild hypothermia (>30°C) by cardiac arrhythmia. However, significant reductions in CMRO₂ do not occur until moderate–deep hypothermia (25–28°C). Selective transarterial hypothermia can overcome the limitations of whole body cooling and has been used as neuroprotection during brain surgery. It can achieve moderate–deep hypothermia while maintaining core temperatures at physiologically acceptable levels. When combined with selective hypothermia, which offers a degree of cooling not achievable with whole body methods, endovascular technology could be a ‘neuroprotective bridge’ in recanalization.

Our study demonstrated that a purely endovascular approach can achieve moderate hypothermia within 30 min. Previous selective hypothermia studies utilized open surgical femoral–carotid bypass, and all reported faster rate and greater depth of hypothermia than in human trials of endovascular transvenous hypothermia. In COOL AID, mean time to achieve a target of 33°C was 77 min, while in ICTUS-L, mean time was 138 min after catheter placement. In both studies, some patients were 8 h post stroke before mild hypothermia was achieved, while target temperatures were only in the mild hypothermia range. Our study demonstrated that a combination of endovascular technology with selective hypothermia allows significant hypothermia (<30°C) within a meaningful time frame for acute stroke intervention.

Tolerance of selective hypothermia

A concern in therapeutic hypothermia is the avoidance of complications, including arrhythmias, coagulopathy, and pneumonia. Most human therapeutic hypothermia protocols are limited to 32–34°C. The degree of systemic cooling seen in our study (mean 34°C) agrees with prior work, and should be tolerable, but measures of this, such as arrhythmia frequency, were not evaluated. Coagulopathy was not assessed as heparin anticoagulation was used during the procedure. A mild but significant decrease was seen in arterial pH. The stability of other factors, such as mean arterial blood pressure, blood oxygenation, and hemoglobin, indicates that placing the endovascular device and utilizing extracorporeal perfusion to induce selective hypothermia did not destabilize the subjects.
Study limitations
The choice of stroke model resulted in three key limitations. First, under lengthy periods of anesthesia, domestic swine develop myocardial depression resulting in frequent use of inotropic support. Interruption of cooling was sometimes required in order to stabilize hemodynamics. Second, the decision to occlude one of several MCA branches created small strokes which, in combination with collateral pathway variation, may have contributed to the wide variance in stroke volumes. Third, reperfusion of the MCA territory was only confirmed by visual inspection. Cerebral perfusion was not measured, and vessel patency following reperfusion was not ensured by indocyanine green or conventional angiography.

The timing of MRI introduces uncertainty. As MRI was post-mortem in this study, T1 and T2 weighted sequences were used.12 Diffusion weighted imaging is the gold standard in stroke, but requires a live animal. The experimental results may reflect changes in reperfusion damage, rather than stroke damage. We measured stroke volumes accurately, but microscopic effects (changes in local chemical substrates) and macroscopic effects (edema or raised intracranial pressure) due to reperfusion were not evaluated. Thus potential effects of hypothermia on reperfusion damage might have been missed.

Future directions
This study raises intriguing questions regarding the efficacy of hypothermia in the face of acute stroke. It would be useful to assess the effect of clipping all MCA branches in terms of stroke volume and variability. The timing of reperfusion deserves clarification. Selective hypothermia could be effective in reducing stroke volumes, even with no recanalization. Finally, performing MRI prior to sacrifice would allow diffusion weighted imaging measurements of stroke volume. Logistic hurdles to this are substantial, as the entire operation, including life support and catheter, would need to be MRI compatible, and transport of an animal potentially on pressors might result in a premature end to the experiment.

CONCLUSION
This is the first study to investigate endovascular technology specifically designed to produce selective brain hypothermia. We have demonstrated that moderate selective hypothermia is rapidly achievable through a completely percutaneous endovascular approach. Times and temperatures correspond well with the results of other animal studies of selective hypothermia using open femoral to carotid bypass. We found a significant reduction in stroke volume by imaging with our intervention. These results suggest that modern endovascular technology, already in place for stroke recanalization, may be a vehicle for hypothermic neuroprotection which in turn may improve stroke outcomes following recanalization.
